References

- Textbook: Chapter 6

Chapter Outline

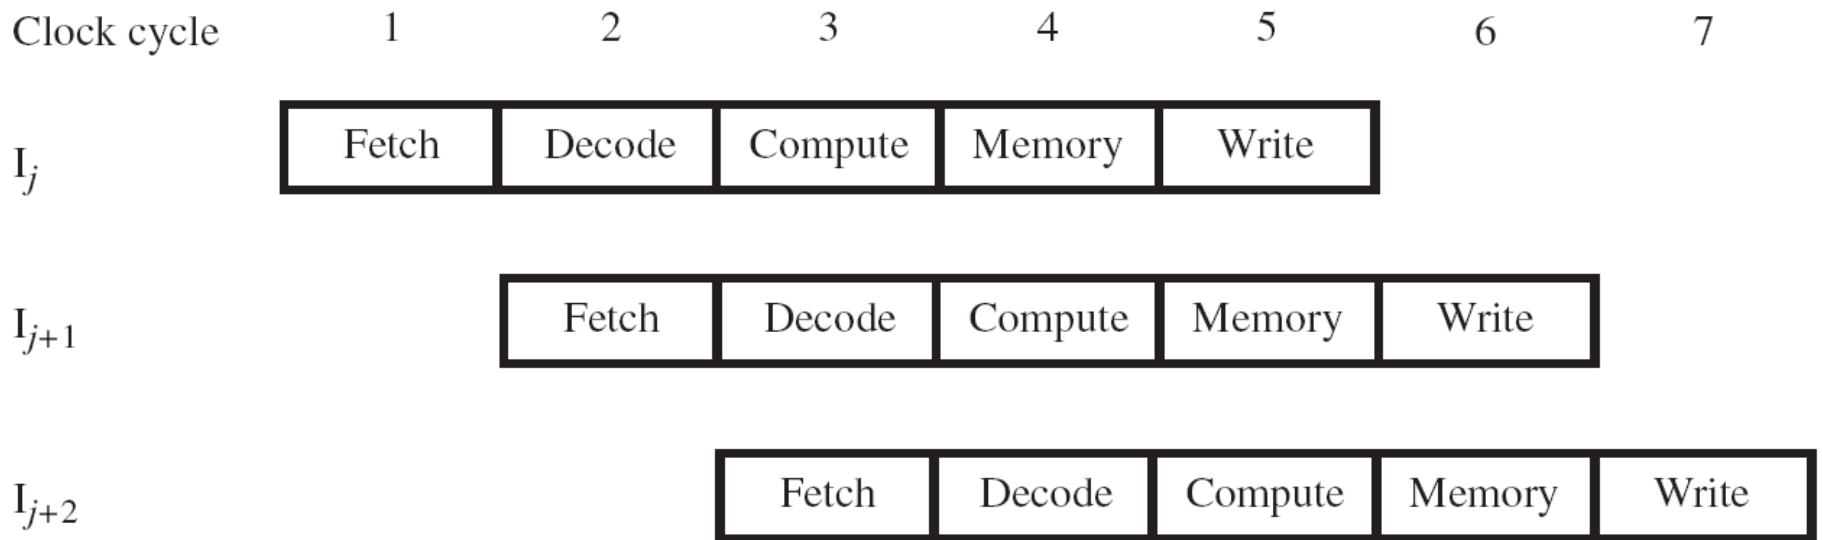

- Pipelining: overlapped instruction execution
- Hazards that limit pipelined performance gain
- Hardware/software implications of pipelining
- Influence of pipelining on instruction sets
- Pipelining in superscalar processors

Basic Concept of Pipelining

- Circuit technology and hardware arrangement influence the speed of execution for programs
- All computer units benefit from faster circuits
- **Pipelining** involves arranging the hardware to *perform multiple operations simultaneously*
- Similar to assembly line where product moves through stations that perform specific tasks
- Same total time for each item, but *overlapped*

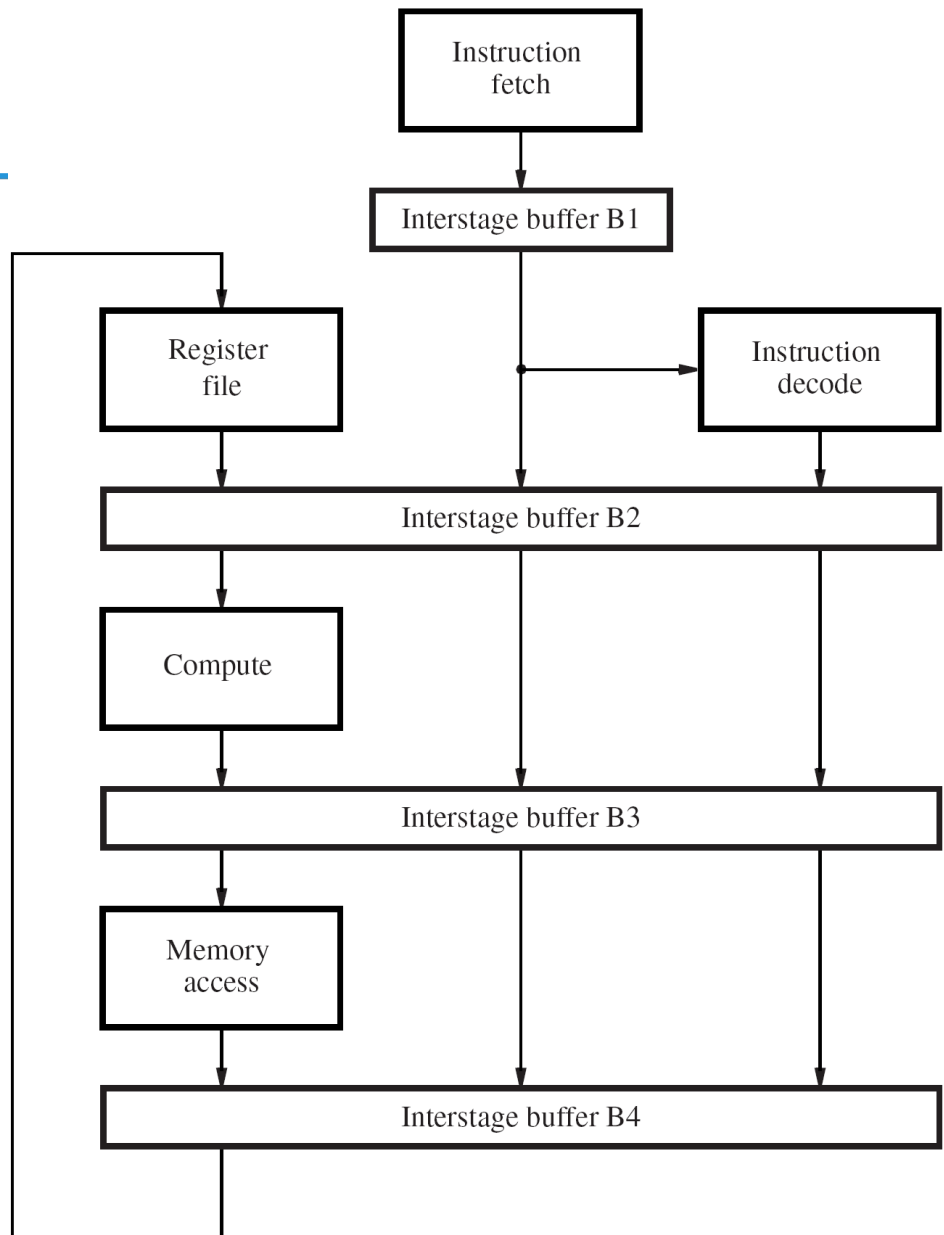

Pipelining in a Computer

- Focus on pipelining of *instruction execution*
- Multistage datapath in Chapter 5 consists of: Fetch, Decode, Compute, Memory, Write
- Instructions fetched & executed one at a time with only one stage active in any cycle
- *With pipelining*, multiple stages are active simultaneously for different instructions
- Still 5 cycles to execute, but *rate* is 1 per cycle

Pipeline Organization

- Use program counter (PC) to fetch instructions
- A new instruction enters pipeline every cycle
- Carry along instruction-specific information as instructions flow through the different stages
- Use *interstage buffers* to hold this information
- These buffers incorporate RA, RB, RM, RY, RZ, IR, and PC-Temp registers from Chapter 5
- The buffers also hold control signal settings

Pipelining Issues

- Consider two successive instructions I_j and I_{j+1}
- Assume that the destination register of I_j matches one of the source registers of I_{j+1}
- Result of I_j is written to destination in cycle 5
- But I_{j+1} reads *old* value of register in cycle 3
- Due to pipelining, I_{j+1} computation is incorrect
- So *stall* (delay) I_{j+1} until I_j writes the new value
- Condition requiring this stall is a *data hazard*

Data Dependencies

- Now consider the specific instructions
 - Add R2, R3, #100
 - Subtract R9, R2, #30
- Destination R2 of Add is a source for Subtract
- There is a *data dependency* between them because R2 carries data from Add to Subtract
- On *non-pipelined* datapath, result is available in R2 because Add completes before Subtract

Stalling the Pipeline

- With pipelined execution, old value is still in register R2 when Subtract is in Decode stage
- So **stall** Subtract for 3 cycles in Decode stage
- New value of R2 is then available in cycle 6

Details for Stalling the Pipeline

- Control circuitry must recognize dependency while Subtract is being decoded in cycle 3
- Interstage buffers carry register identifiers for source(s) and destination of instructions
- In cycle 3, compare destination identifier in Compute stage against source(s) in Decode
- R2 matches, so Subtract kept in Decode while Add allowed to continue normally

Details for Stalling the Pipeline

- Stall the Subtract instruction for 3 cycles by keeping contents of interstage buffer B1
- What happens after Add leaves Compute?
- Control signals are set in cycles 3 to 5 to create an *implicit* NOP (No-operation) in Compute
- NOP control signals in interstage buffer B2 create a cycle of idle time in each later stage
- The idle time from each NOP is called a *bubble*

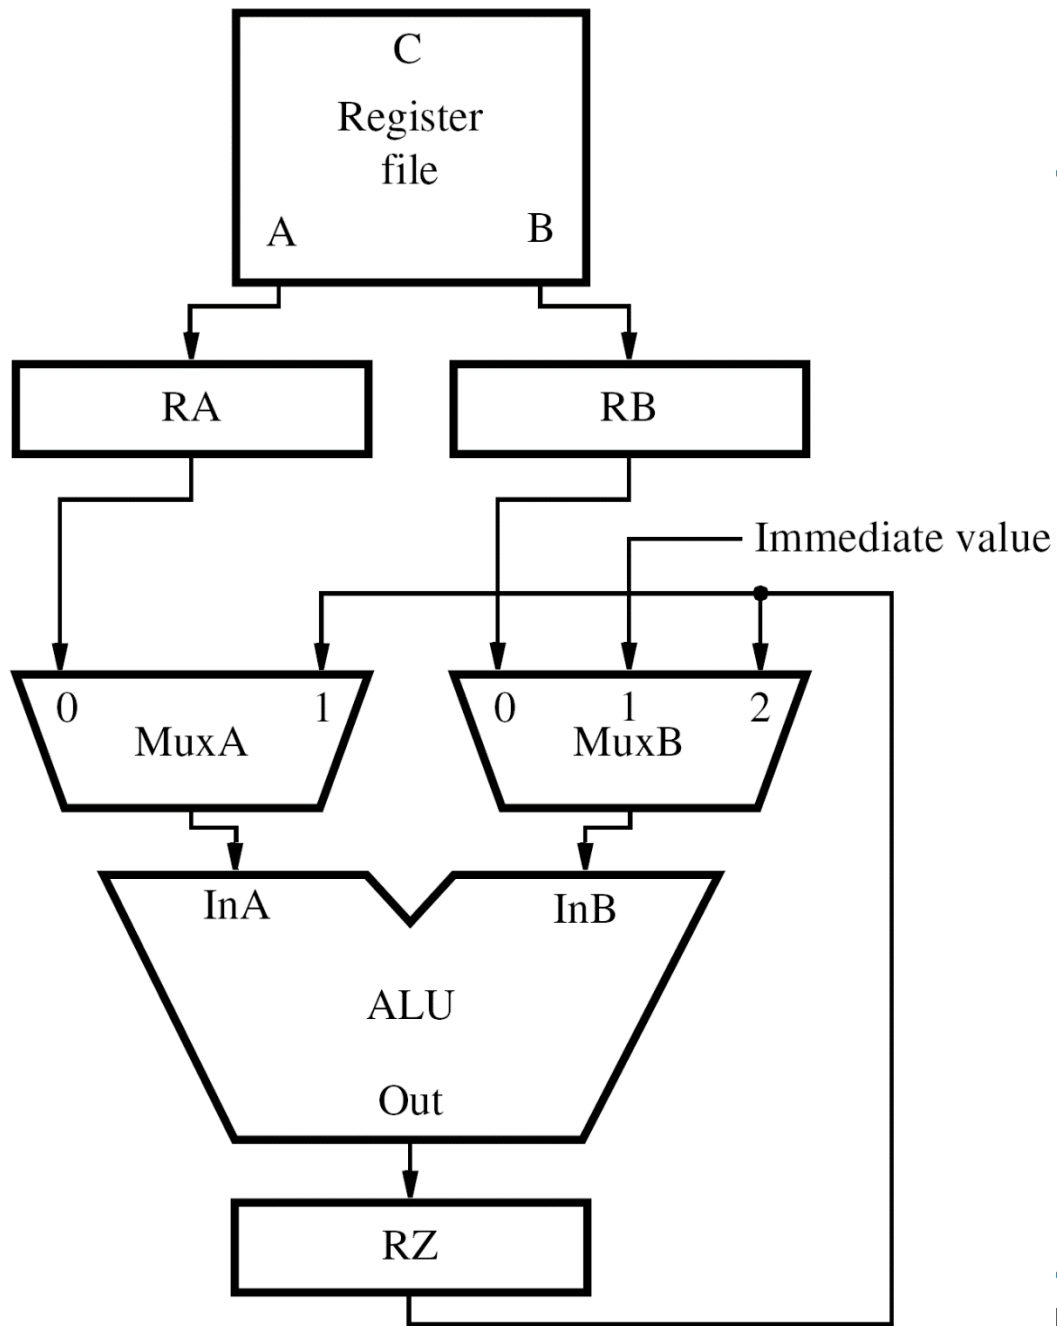

Operand Forwarding

- **Operand forwarding** handles dependencies without the penalty of stalling the pipeline
- For the preceding sequence of instructions, new value for R2 is available at end of cycle 3
- *Forward* value to where it is needed in cycle 4

Details for Operand Forwarding

- Introduce multiplexers before ALU inputs to use contents of register RZ as forwarded value
- Control circuitry now recognizes dependency in cycle 4 when Subtract is in Compute stage
- Interstage buffers still carry register identifiers
- Compare destination of Add in Memory stage with source(s) of Subtract in Compute stage
- Set multiplexer control based on comparison

Software Handling of Dependencies

- Compiler can generate & analyze instructions
- Data dependencies are evident from registers
- Compiler puts three *explicit* NOP instructions between instructions having a dependency
- Delay ensures new value available in register but causes total execution time to increase
- Compiler can *optimize* by moving instructions into NOP slots (if data dependencies permit)

Memory Delays

- Memory delays can also cause pipeline stalls
- A cache memory holds instructions and data from the main memory, but is faster to access
- With a cache, typical access time is one cycle
- But a cache *miss* requires accessing slower main memory with a much longer delay
- In pipeline, memory delay for one instruction causes subsequent instructions to be delayed

Memory Delays

- Even with a cache *hit*, a Load instruction may cause a short delay due to a data dependency
- One-cycle stall required for correct value to be forwarded to instruction needing that value
- Optimize with useful instruction to fill delay

Branch Delays

- Ideal pipelining: fetch each new instruction while previous instruction is being decoded
- Branch instructions alter execution sequence, but they must be processed to know the effect
- Any delay for determining branch outcome leads to an increase in total execution time
- Techniques to mitigate this effect are desired
- Understand branch behavior to find solutions

Unconditional Branches

- Consider instructions I_j , I_{j+1} , I_{j+2} in sequence
- I_j is an unconditional branch with target I_k
- In Chapter 5, the Compute stage determined the target address using offset and $PC+4$ value
- In pipeline, target I_k is known for I_j in cycle 4, but instructions I_{j+1} , I_{j+2} fetched in cycles 2 & 3
- Target I_k should have followed I_j immediately, so discard I_{j+1} , I_{j+2} and incur two-cycle *penalty*

Reducing the Branch Penalty

- In pipeline, adder for PC is used every cycle, so it cannot calculate the branch target address
- So introduce a second adder just for branches
- Place this second adder in the Decode stage to enable earlier determination of target address
- For previous example, now only I_{j+1} is fetched
- Only one instruction needs to be discarded
- The branch penalty is reduced to one cycle

Conditional Branches

- Consider a conditional branch instruction:
Branch_if_[R5]=[R6] LOOP
- Requires not only target address calculation, but also requires comparison for condition
- In Chapter 5, ALU performed the comparison
- Target address now calculated in Decode stage
- To maintain one-cycle penalty, we introduce a comparator just for branches in Decode stage

The Branch Delay Slot

- Let both branch decision and target address be determined in Decode stage of pipeline
- Instruction immediately following a branch is always fetched, regardless of branch decision
- That next instruction is discarded with penalty, except when conditional branch is not taken
- The location immediately following the branch is called the *branch delay slot*

The Branch Delay Slot

- Instead of conditionally discarding instruction in delay slot, *always* let it complete execution
- Let compiler find an instruction *before* branch to move into slot, if data dependencies permit
- Called *delayed branching* due to reordering
- If useful instruction put in slot, penalty is *zero*
- If not possible, insert explicit NOP in delay slot for one-cycle penalty, whether or not taken

Add R7, R8, R9
Branch_if_[R3]=0 TARGET
 I_{j+1}
⋮

TARGET: I_k

(a) Original sequence of instructions containing a conditional branch instruction

Branch_if_[R3]=0 TARGET
Add R7, R8, R9
 I_{j+1}
⋮

TARGET: I_k

(b) Placing the Add instruction in the branch delay slot where it is always executed

Branch Prediction

- A branch is decided in Decode stage (cycle 2) while following instruction is *always* fetched
- Following instruction may require discarding (or with delayed branching, it may be a NOP)
- Instead of discarding the *following* instruction, can we anticipate the *actual* next instruction?
- Two aims: (a) *predict* the branch decision
(b) use prediction *earlier* in cycle 1

Static Branch Prediction

- Simplest approach: assume branch *not* taken
- Penalty if prediction disproved during Decode
- If branches are random, accuracy is 50%
- But a branch at end of a loop is usually taken
- So for backward branch, always predict *taken*
- Use target address as soon as it is available
- Expect higher accuracy for this special case, but what about accuracy for other branches?

Dynamic Branch Prediction

- Idea: track branch decisions during execution for *dynamic* prediction to improve accuracy
- Simplest approach: use most recent outcome for likely taken (LT) or likely not-taken (LNT)
- For branch at end of loop, we mispredict in last pass, and in first pass if loop is *re-entered*
- Avoid misprediction for loop re-entry with four states (ST, LT, LNT, SNT) for strongly/likely
- Must be wrong *twice* to change prediction

Branch not taken (BNT)

(a) A 2-state algorithm

(b) A 4-state algorithm

Branch Target Buffer

- Prediction only provides a presumed *decision*
- Decode stage computes *target* in cycle 2
- But we need target (and prediction) in cycle 1
- *Branch target buffer* stores target address and history from *last* execution of each branch
- In cycle 1, use branch instruction address to look up target and use history for prediction
- Fetch in cycle 2 using prediction; if mispredict detected during Decode, correct it in cycle 3

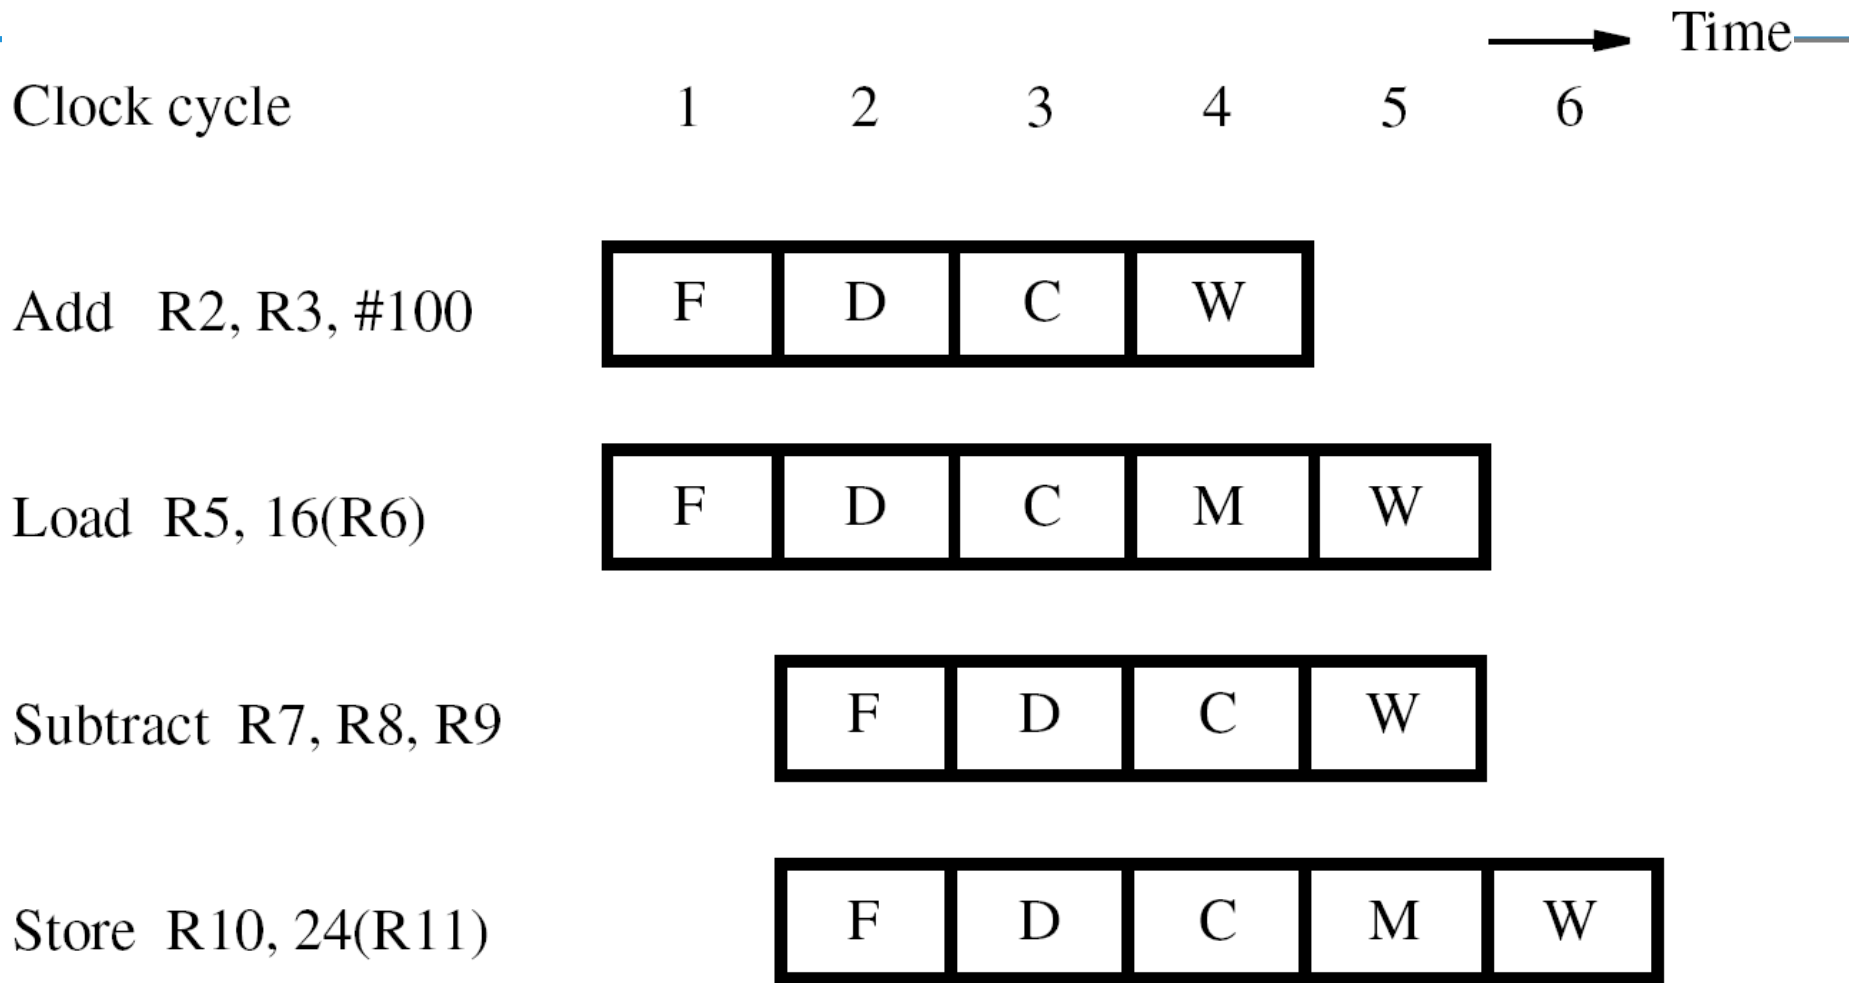

Superscalar Operation

- Introduce multiple execution units to enable *multiple instruction issue* for > 1 instr./cycle
- This organization is for a **superscalar processor**
- An elaborate *fetch unit* brings 2+ instructions into an instruction queue in every cycle
- A *dispatch unit* takes 2+ instructions from the head of queue in every cycle, decodes them, sends them to appropriate execution units
- A *completion unit* writes results to registers

Superscalar Operation

- Minimum superscalar arrangement consists of a Load/Store unit and an arithmetic unit
- Because of Index mode address calculation, Load/Store unit has a two-stage pipeline
- Arithmetic unit usually has one stage
- For two execution units, how many operands?
- Up to 4 inputs, so register file has 4 read ports
- Up to 2 results, so also need 2 write ports (and methods to prevent write to same reg.)

Branches and Data Dependencies

- With no branches or data dependencies, interleave arithmetic & memory instructions to obtain maximum throughput (2 per cycle)
- But branches do occur and must be handled
- Branches processed entirely by fetch unit to determine which instructions enter queue
- Fetch unit uses prediction for all branches
- Necessary because decisions may need values produced by other instructions in progress

Branches and Data Dependencies

- *Speculative execution*: results of instructions not committed until prediction is confirmed
- Requires extra hardware to track speculation and to recover in the event of misprediction
- For data dependencies between instructions, the execution units have *reservation stations*
- They buffer register identifiers and operands for dispatched instructions awaiting execution
- Broadcast results for stations to capture & use

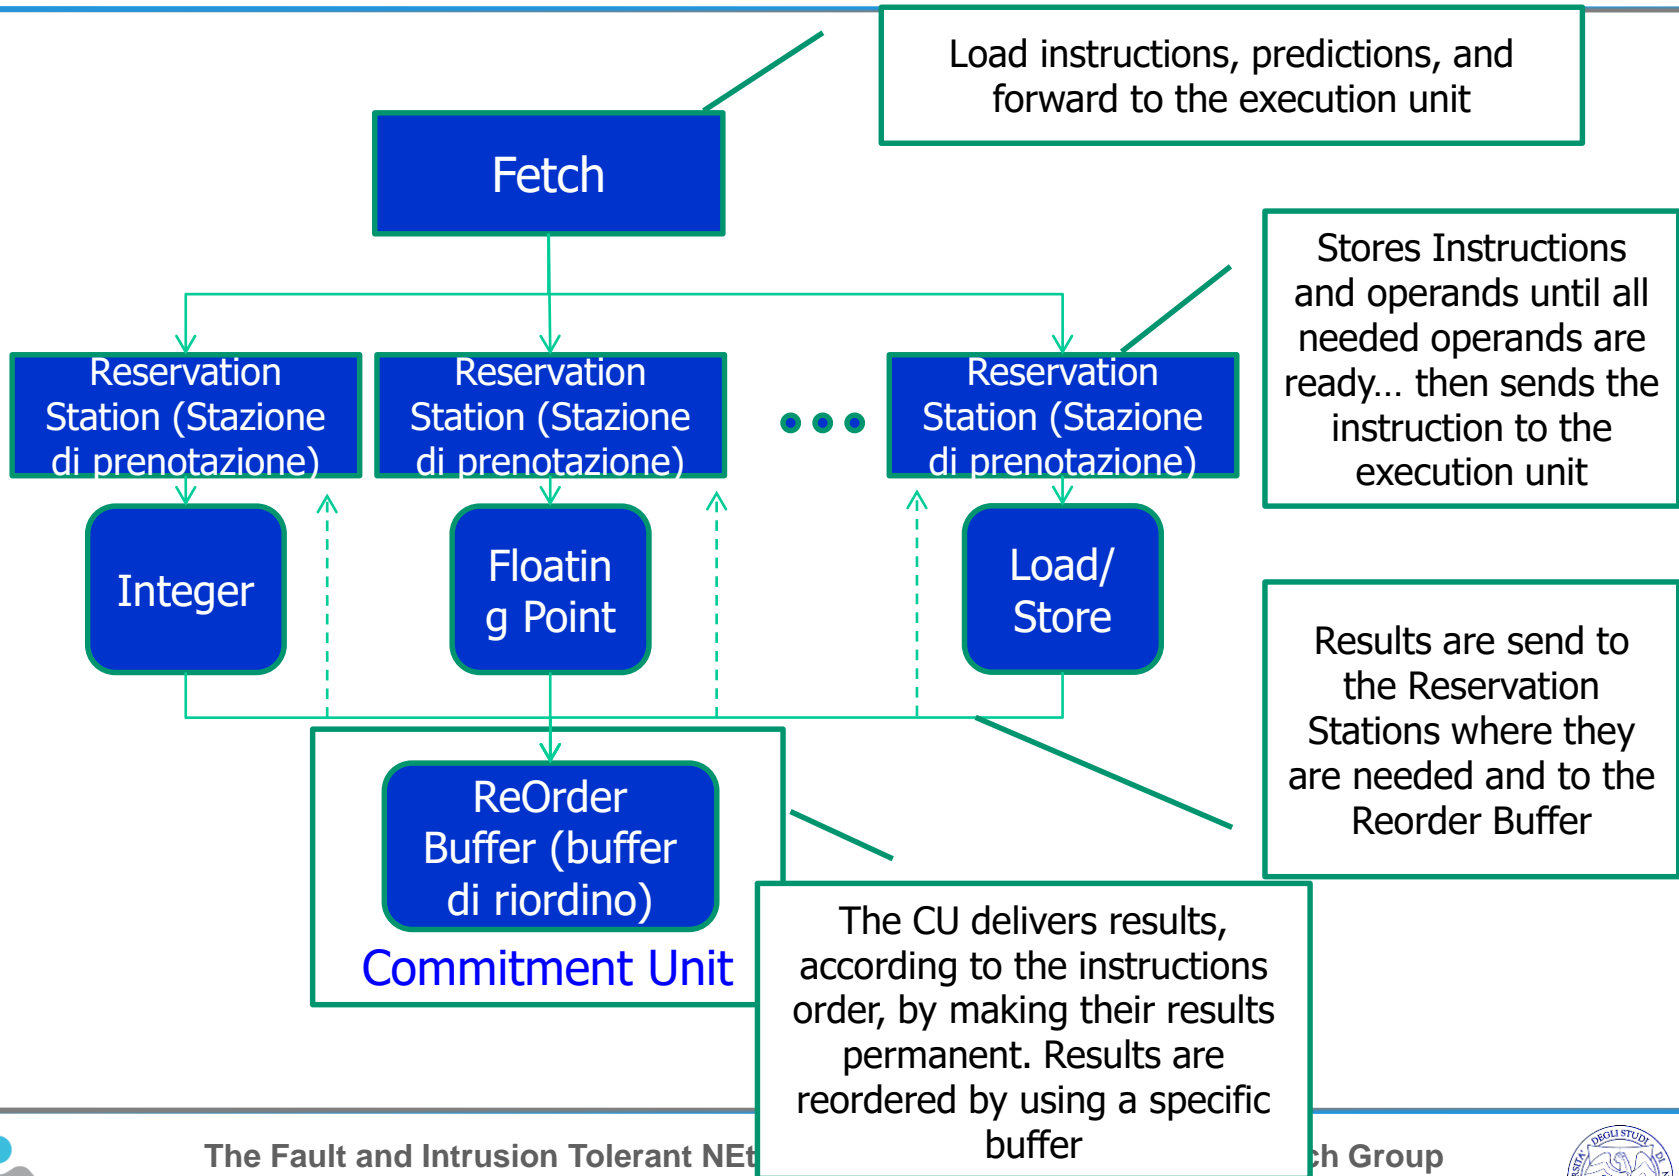

Out-of-Order Execution

- With instructions buffered at execution units, should execution reflect original sequencing?
- If two instructions have no dependencies, there are no actual ordering constraints
- This enables *out-of-order execution*, ...

Out-of-Order Execution

- With instructions buffered at execution units, should execution reflect original sequencing?
- If two instructions have no dependencies, there are no actual ordering constraints
- This enables *out-of-order execution*, but then leads to *imprecise exceptions* in program state
 - for example the load can generate an error while accessing a non aligned word but the subtract has already changed the value of R7
- For *precise exceptions*, must commit results strictly in original order with extra hardware

Execution Completion

- To commit results in original program order, superscalar processors can use 2 techniques
- *Register renaming* uses temporary registers to hold new data before it is safe for final update
 - Can be less than the real registers (and allowed upon requested)
- *Reorder buffer* in commitment unit is where dispatched instructions placed in strict order
- Update the actual destination register only for instruction at head of queue in reorder buffer
- Ensures instructions *retired* in original order

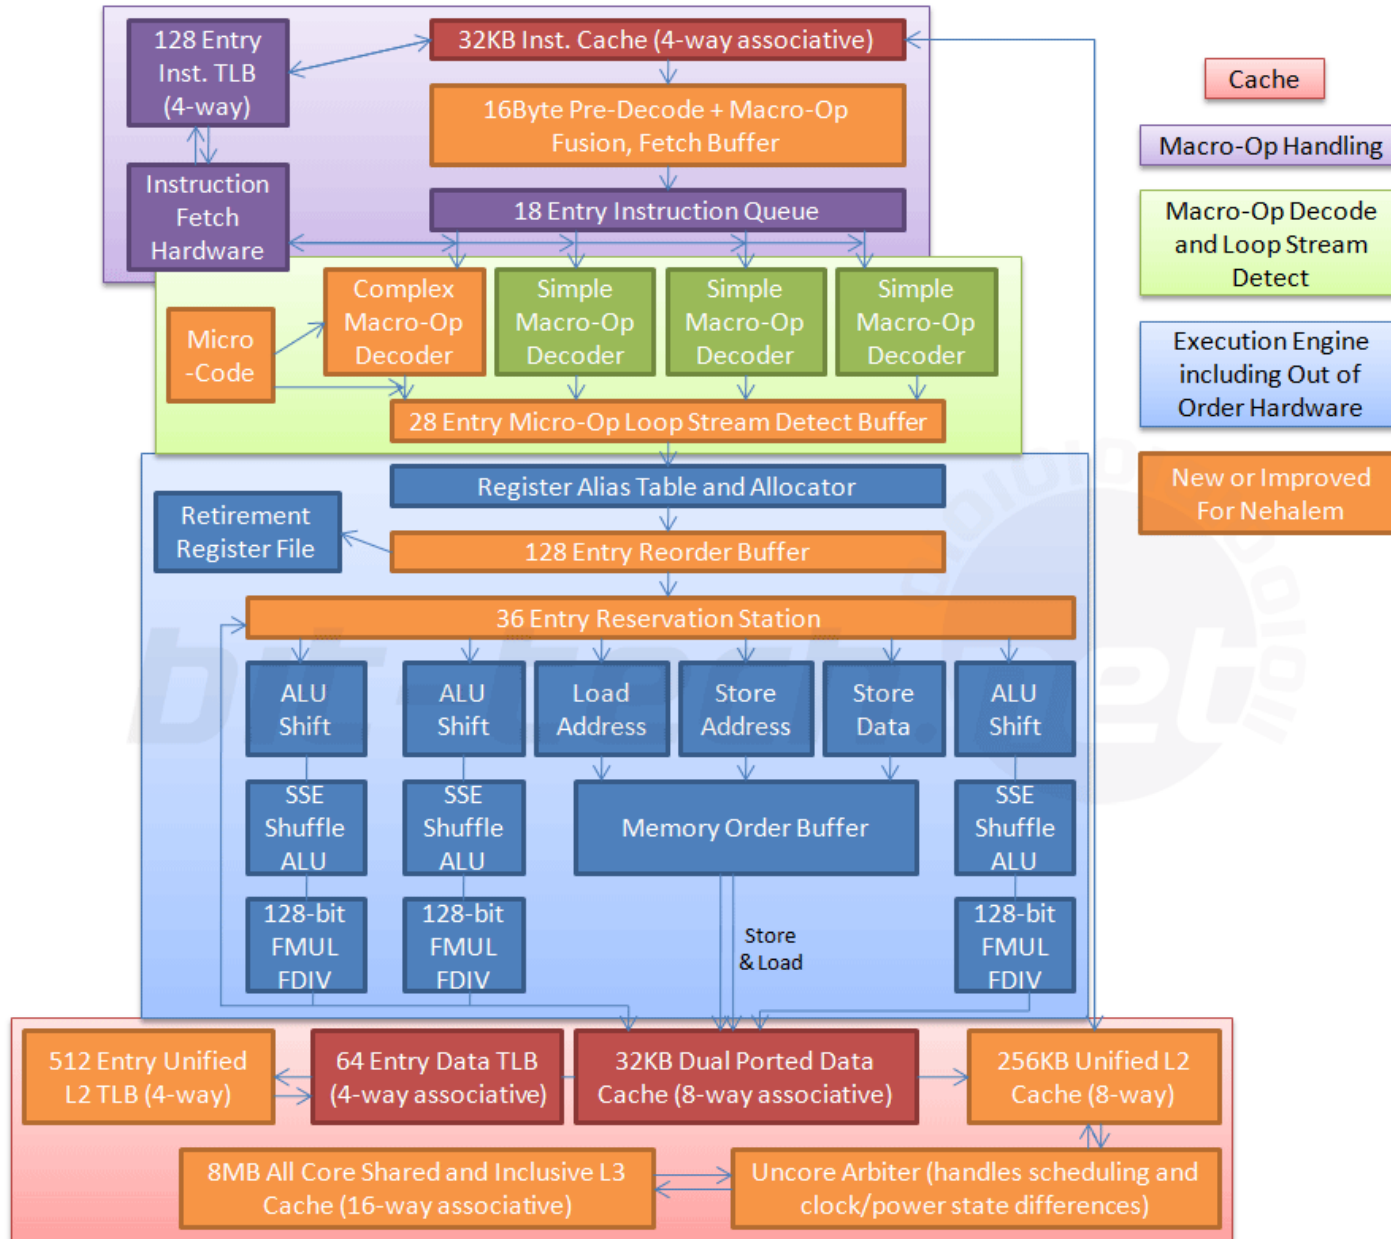

Dispatch Operation

- Dispatch of instruction proceeds only when all needed resources available (temp. register, space in reservation station & reorder buffer)
- If instruction has some but not all resources, should a subsequent instruction proceed?
 - E.g. the LOAD execution unit is full, can the Subtract be send for execution?
- Decisions must avoid *deadlock* conditions (two instructions need each other's resources)
- More complex, so easier to use original order, particularly with more than 2 execution units

Pipelining in CISC Processors

- Load/Store architecture simplifies pipelining; influenced development of RISC processors
- CISC processors introduce complications from instructions with multiple memory operands and side effects (autoincrement, cond. codes)
 - More words for a single instruction, Variable length instructions,
- But existing CISC architectures later pipelined (with more effort) after development of RISC
- Examples: Freescale ColdFire and Intel IA-32

Intel I7 Pipeline [\(<http://www.bit-tech.net/hardware/cpus/2008/11/03/intel-core-i7-nehalem-architecture-dive/5>\)](http://www.bit-tech.net/hardware/cpus/2008/11/03/intel-core-i7-nehalem-architecture-dive/5)

Concluding Remarks

- Pipelining overlaps activity for 1 instr./cycle
- Combine it with multiple instruction issue in superscalar processors for >1 instr./cycle
- Potential performance gains depend on:
 - instruction set characteristics
 - design of pipeline hardware
 - ability of compiler to optimize code
- Interaction of these aspects is a key factor
